# The Stakes of Scrying: `. ^ dotket` and the Seer Proposal

Ted Blackman `~rovnys-ricfer` and Paul Driver `~fodwyt-ragful`  
Urbit Foundation

## Abstract

Nock 12 and the `. ^ dotket` rune break the referential transparency of Nock, with consequences for the purity of Urbit’s functional programming model. We consider the implications of this, and propose a move-based replacement for `. ^ dotket` that would restore referential transparency to Nock.

## 1 Introduction

While Nock formally has twelve opcodes, numbered 0–11, it is convenient to expose in userspace a fake Nock 12 opcode to expose the scry namespace to userspace developers. This opcode is trivially invoked by using the Hoon `. ^ dotket` rune. However, Nock 12 breaks the referential transparency of Nock, and this has consequences for the purity of Urbit’s functional programming model.

## 2 How . ^ dotket Works

The Nock 12 opcode and the . ^ dotket rune are used by userspace code to ask the kernel for data in the scry namespace.<sup>1</sup> When Urbit runs userspace code, that code is not raw Nock. It is instead called Mock, which is Nock with two additions: deterministic errors are caught and returned as values to the kernel; and there is an extra Nock opcode, opcode 12. A simple Nock 12 formula looks like [12 [1 /foo/bar/baz]], where /foo/bar/baz is a path literal [%foo %bar %baz ~], representing a path in the scry namespace. The result of running this opcode will be the result of performing the scry request, i.e. dereferencing the path.

Catching deterministic errors is uncontroversial, but the Nock 12 opcode poses some difficulties and has been under scrutiny for years now. The most tangible problem with Nock 12 is that it prevents userspace code from persistently memoizing Nock computations; at the moment, only kernelspace code can hold onto Nock memoization caches across multiple Arvo events. The lifetime of a userspace memoization cache is limited to a single metacircular evaluation context, i.e. a single call to ++mink or an equivalent gate that runs Mock (virtual Nock with the extra opcode).

Userspace code cannot memoize Nock persistently because it is not feasible for the runtime to prevent a jet mismatch in the metacircular evaluator gate. A gate like ++mink takes in a Mock expression (a cell of [subject formula]) and a "scry handler gate" (which is described shortly), and returns a value which is one of:

- [0 computation-result] for a successful evaluation;
- [1 block] in the case of a failed scry request; or
- [2 error] in the case of a deterministic error.

While error handling is not relevant to the current question, a brief description is included here for thoroughness. The error in ++mink's result [2 error] is a deterministic error, meaning that every attempt to evaluate that [subject formula] pair will always result in that same error value—deterministic errors correspond to the lines in the Nock spec where \*a evaluates to \*a, i.e. a trivial infinite loop. Non-deterministic errors, such as running out of usable memory or getting interrupted by the user, result in the function failing to complete, and the Arvo event will be aborted and rolled back to its state before trying to run this new event.

As mentioned, the [subject formula] pair is not the only input to ++mink. There is also an argument of the form scry=\$-(^ (unit (unit))), called the scry handler gate. When ++mink encounters a Nock 12 opcode while evaluating the [subject formula] expression, it evaluates the sub-formula to obtain a path to look up in the scry namespace. Once it has this path, it calls the scry handler gate on the path, which returns one of:

- [~~value] positive scry response;
- [~~] permanent scry failure; or

---

<sup>1</sup>The scry namespace, in brief, is a TODO bound

62 • ~ “block”.

63 The positive response case means that the scry was performed successfully and yielded  
64 a value, in which case ++mink injects the value as the result of the Nock 12 opcode  
65 and continues to evaluate the Nock. The permanent failure means the scry namespace  
66 knows there will never be a value at that path, so ++mink can immediately return a  
67 deterministic error.

68 A scry block means the system refused to answer the question, i.e. the request  
69 was “blocked” for some reason—this could be due to lack of permission, or because  
70 the request asked about the future, or the request asked for data from another ship  
71 that isn’t synchronously available within this Arvo event. If the scry blocks, ++mink  
72 returns a [1 block], where block is the scry request path whose value could not  
73 be resolved.

74 The Nock 12 opcode is problematic because it renders the result of the computation  
75 dependent on external data which are not in the [subject formula] that is being  
76 evaluated. The result is no longer a pure function of the subject and formula:  
77 depending on what the scry handler gate is, the same [subject formula] could  
78 yield different results. Consider [subject formula] of [0 [12 1 /foo/bar]].  
79 This returns the result of looking up the /foo/bar scry request path from the scry  
80 gate. Userspace code (which is untrusted) could call (mink [[0 12 1 /foo/bar]]  
81 |= (^ [~~33])), acquire the result 33, then call (mink [[0 12 1 /foo/bar]]  
82 |= (^ [~~44])) to yield 44. The subjects and formulas were identical, but  
83 because they were evaluated with different scry gates, they yielded different results.

84 Given that Urbit is supposed to be a pure-functional system, how can this be ac-  
85 ceptable? The answer is that Mock, virtual Nock, is purely functional (mathemati-  
86 cally, a “partial function” like Nock itself) as long as it’s only ever run using the real  
87 scry namespace, which is referentially transparent. That is to say, all data in the scry  
88 namespace can be thought of as something like axiomatic data that everyone agrees  
89 on and never changes: all virtual Nock computations will get the same answers to all  
90 Nock 12 opcodes that complete, because everyone agrees on which value is bound to  
91 each path in the namespace.

92 You could alternatively think of the scry namespace as an extra implicit argument  
93 passed to every Mock computation along with the subject and formula. This extra  
94 argument is discovered dynamically over time as more ships bind more values, but  
95 since any path can only be bound once, it’s immutable and all Mock expressions that  
96 dereference some scry path will either fail to complete or complete with identical  
97 results, hence pure functional.

98 Note that there’s no requirement that all the scry gates be noun-equivalent (inten-  
99 sionally equal), or even contain the same set of namespace paths and values (exten-  
100 sionally equal). The requirement is that no two scry gates ever return different values  
101 for any given scry request path.<sup>2</sup>

102 The Arvo kernel’s scry handler gate, as described in the original Moron Lab blog  
103 post about Urbit [~sorreg-namtyv, 2010], is a “static functional namespace”, so

<sup>2</sup>A scry gate that always blocks is trivially legitimate, since it never gives any answers, much less answers that differ from those of another scry gate.

104 even though that gate changes frequently, it maintains the invariant that every scry  
105 path's binding to a value is immutable.<sup>3</sup>

106 As long as a correct Arvo kernel is supplying the scry handler, Mock retains its  
107 purely functional nature. But consider again the case where userspace code runs the  
108 same `[subject formula]` twice, but with two different scry gates that give dif-  
109 ferent answers to some scry path. From the perspective of a simple Nock interpreter,  
110 it's still deterministic: `++mink` is just some Nock function that runs some other com-  
111 putation (Mock) on some inputs. Because it's just some Nock function, it can't break  
112 determinism of the Arvo event; replaying the Arvo event will still yield the same  
113 result. The problem only arises when trying to get clever about how the runtime  
114 evaluates Nock, in particular by caching the results of Nock computations.

115 Development versions of Vere support persistent Nock memoization. This means  
116 a programmer can emit a Nock hint to the interpreter asking the interpreter to cache  
117 the result of the computation, so that if it gets run again, the result will be retrieved  
118 from the runtime's cache instead of rerun step by step. The cache key is a `[subject`  
119 `formula]` pair. When the interpreter sees a `%memo` hint, it looks at the `[subject`  
120 `formula]` that the hint surrounds. If the memoization cache has a value for that key,  
121 the runtime uses that value as the result of the computation. Otherwise the runtime  
122 runs the computation, inserts the result into the cache, and returns the result.

123 For the moment, only the kernel can place items into the cache. Userspace code  
124 runs Mock, so if it were allowed to place items into the cache, there would be three  
125 options:

- 126 1. Let userspace code place arbitrary values into the cache. This poses a severe  
127 security problem: event replay would be nondeterministic, influenced by the  
128 contents of the memoization cache, allowing malicious userspace agents to per-  
129 form a kind of denial of service attack by preventing event replay, or possibly  
130 even worse, by injecting cache lines that other applications would use, causing  
131 those other applications to malfunction in a way the malicious code wants. The  
132 worst case would be causing a system app such as `%hood` to fail to enforce a  
133 security check, allowing the malicious code to escalate its own privileges and  
134 permitting it to ask the system app to do something like reinstall the kernel.
- 135 2. Place the scry gate into the cache key for the memoization cache, so a cache  
136 key would be `[[subject formula] scry-gate]` instead of just `[subject`  
137 `formula]`. This would close the security hole, but since Arvo's scry gate un-  
138 dergoes small changes on between every agent activation, it would make these  
139 cache lines useless outside of the immediate execution context within a single  
140 `++mink` call. This is exactly the situation userspace code is already in, and thus  
141 not helpful at all.
- 142 3. Have the interpreter record the set of scry `[path value]` pairs looked up by  
143 the computation. This would allow userspace code to perform scry requests  
144 safely, but the cost is a nontrivial amount of machinery in the runtime, along

---

<sup>3</sup>Up to some known flaws that are addressed by UIP-0116: Arvo Ticks [[~wicdev-wisryt](#) and  
[~rovnyis-ricfer](#), 2023a,b, [~midden-fabler](#), 2024].

with a computational cost of looking up a cache line that grows linearly with the number of scry paths that were requested. Of the three options listed here, this is the most reasonable, but it is still highly nontrivial and the requirement to compare all requested paths could be onerous.

Instead of implementing any of these options, Urbit has currently simply disabled the ability for userspace code to modify the Nock memoization cache. This is enforced by the jet for `++mink`; the jet is simply a call back into the normal Nock interpreter, which is really a Mock interpreter, whose state includes a list of nouns representing the stack of scry handler gates for the current execution context. If this list is null `~`, then we must be in the kernel and the code is allowed to modify the memoization cache; otherwise, we are in some kind of Mock context, and the code is not allowed to modify the cache.

The concerns with `. ^ dotket` go deeper than memoization however, despite that being the only known major concrete issue.<sup>4</sup> Conceptually, the fact that a Mock computation has implicit external dependencies makes the pure-functional nature of the system more fragile—the memoization issue is downstream of this fragility.

Morally and aesthetically, the fact that Nock makes no assumptions about any of its contents is part of the magic of Urbit. Nock is a true functional programming language with no implicit external dependencies at all, and no constraints on the nouns it operates on. Anything that pollutes this vision is potentially harmful to the environment Urbit creates for programs and their authors. Mock’s implicit dependency on the namespace makes Nock context-dependent instead of context-independent, as it should be. A related issue is that userspace code does not have access to raw Nock, only Mock. The Hoon compiler willingly outputs Nock 12 instructions when handed a `. ^ dotket` rune, and there is no means for userspace code to signal that it will refrain from using Nock 12.

### 3 Recommendations

The removal of Nock 12 is fraught with difficulty for userspace and kernel development. The core development team has considered two proposals which will allow the kernel to gracefully deprecate Nock 12. The two concrete lines of action are:

1. Add a new metacircular evaluator gate that does not run Nock 12 expressions (the Seer proposal).
2. Add a move-based interface for scrying to the Gall interface.

This approach will allow core developers and userspace application developers to experiment with code that does not use `. ^ dotket`. If that resulting code and associated design patterns work well, we will deprecate the `. ^ dotket` rune and the Nock 12 opcode in favor of move-based scrying.

---

<sup>4</sup>Some complexity is introduced in the runtime when jetting the metacircular interpreter.

### 3.1 The Seer Monad

Seer is a monadic scry interface which allows application developers to read from the namespace without using `.^ dotket` or its virtual Nock operator 12. Userspace code run inside of this gate can reestablish the guarantee that it is purely functional, allowing it to modify the memoization cache.<sup>5</sup>

Seer is designed as a replacement for `.^ dotket`, and thus attempts to be as ergonomic as the `.^ dotket` pattern. Consider a Gall agent that scries using the current `.^ dotket` pattern:

```
++ on-poke
  |= [m=mark v=vase]
  ^- (quip card _this)
  =/ foo-result .^ @da /cx/(now)/foo
  :: do something with foo-result...
  [~ this]
```

A corresponding snippet of a Gall agent that scries using `++seer` in the continuation style would look like this:

```
++ gear          :: gall seer
  |* a=mold
  (seer vase a)
++ on-poke
  |= [m=mark v=vase]
  ^- (gear (quip card _this)) :: (seer vase (quip card _this))
  :+ %scry /cx/(now)/foo |= foo=vase
  =/ foo-result !<(@ foo)
  :: do something with foo-result...
  [%done ~ this]
```

`++seer` values can be composed using a monadic bind:

```
++ foo ^- (seer vase @) !! :: /foo
++ bar ^- (seer vase @) !! :: /bar
++ on-poke
  |= [m=mark v=vase]
  =* r (quip card _this)
  ^- (gear r)
  =/ bind (rapt vase r)
  ;< foo=@ bind foo
  ;< bar=@ bind bar
  [%done ~ this(some-state (add foo bar))]
```

(In this example, use is made of `++rapt`. `++rapt` is a monadic scry binding gate [~mastyrbottec, 2023c].)

Here, a `++seer` is the type of programs that scry:

<sup>5</sup>Note that it's still acceptable for that gate to be called from Mock code, or even nested Mock code, that had previously performed scry requests that were not referentially transparent: raw Nock is context-free, so no matter how the [subject formula] cell was created, the result of its evaluation is still pure.

```

222 ++ seer
223 |* [r=mold a=mold]
224 $~ [%done *a]
225 $% [%done p=a]
226 [%scry p=path k=$(r (seer r a))]
227 ==

```

228 The ++seer scry system is intentionally incompatible with the current . ^ dotket scry  
229 system. We believe that ++seer degrades ergonomics only slightly. In the initial in-  
230 troduction, we shall provide a wrapper library which accepts an agent written in the  
231 ++seer style and produces an agent that scries in the . ^ dotket style.

232 The current reference implementation of Seer is available at ~mastyr-bottec  
233 [2023a]. A more complete example is available at ~mastyr-bottec [2023b].

## 234 3.2 Move-Based Scry Interface

235 A Gall agent will be able to emit a new kind of move, in addition to all the moves it can  
236 emit now, that asks Gall to perform a scry request on the agent’s behalf. When Gall  
237 processes this move, it will perform the scry request and convert the result of the scry  
238 into a response move that will be delivered back into the agent in a later activation  
239 of the Gall vane, in accordance with the normal move processing order that Gall and  
240 Arvo use. Thus an agent could emit a list of moves such as [poke-1 scry-A poke-  
241 2 scry-B poke-3 ~] and Gall will handle all of those moves in the same order as  
242 if they were all pokes, i.e. the kernel will not introduce any exceptions to its normal  
243 move processing order for scry request moves.

244 This proposal is less developed than the Seer proposal, and thus no code examples  
245 can be provided, and no reference implementation exists at the time of writing.

## 246 4 Conclusion

247 There is a general consensus among Urbit core developers that a new move-based  
248 scry interface is better suited as the lowest layer of the scry system than the Seer  
249 monadic interface. The fact that Seer or . ^ dotket<sup>6</sup> could be implemented on top  
250 of moves (but not necessarily the other way around) militates in favor of moves at  
251 the lowest layer. Another benefit of this arrangement is that by making all scrys  
252 asynchronous, the same interface can be used for both local and remote scrys (since  
253 remote scrys are always asynchronous). Such an abstraction over local vs. remote  
254 scry calls removes what would otherwise be an unavoidable branch point in userspace  
255 I/O code. It also matches the rest of Gall’s interprocess communication model, which  
256 does not distinguish between local and remote. A strong argument can be made that  
257 this is also the most “grug-brained” option, which is not to be undervalued.

258 There remain concerns about application development patterns if . ^ dotket is  
259 removed. Losing synchronous read access to other parts of the system potentially  
260 reduces the ergonomic wins of a naturally growing transaction across applications.

<sup>6</sup>Or at least an opt-in form of Mock, rather than it being the global default as it is now.

This can be implemented in a way that is almost synchronous for local scrys, and in particular it is still possible to perform multiple scry requests at the same system snapshot, meaning the requesting agent will see a consistent view of the system without any tearing.

Gall will also need to run the `++on-peek` arm of a Gall agent in the Seer monad, i.e. that arm will return either `[%done scry-result]` to indicate it's done or `[%scry scry-request-path callback]` to ask Gall to perform a scry request, in which case Gall performs the scry, injects the result into the callback gate, and repeats, until a `%done` is returned. This should not be a direct problem, but betokens complexity creeping into the Gall interface.

Because of these concerns with the proposed move-based replacement for `.^ dotket`, we will first add it as a new feature alongside `.^ dotket` before committing to removing `.^ dotket`. In this way, if the application patterns end up suffering inordinately, `.^ dotket` may be retained. That being said, the current primary plan is to deprecate `.^ dotket` once move-based scrying has been verified as providing a sufficiently good application model. This is a conservative, incremental approach that will not break any existing code and lets us try out the new style in production applications before committing to the removal of Nock 12.
